Example. A robot arm solders chips on a board in *n* contact points. We want to minimize the time to attach a chip to the board, knowing that • The arm moves at constant speed; • Once a chip has been attached another one is soldered; Defining the Input and Output: • Input: a set *S* of *n* points in the plane • Output: the shortest path visiting all the points in *S*

```
Algorithm. (Nearest neighbor)

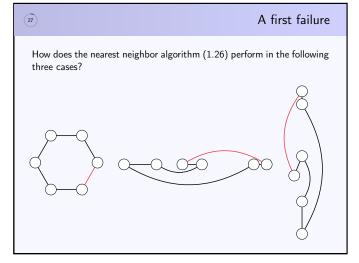

Input: a set S = \{s_0, \cdots, s_{n-1}\} of n points in the plane

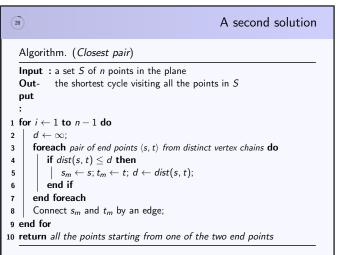

Out- the shortest cycle visiting all the points in S

put:

1 p_0 \leftarrow s_0;
2 for i \leftarrow 1 to n-1 do

3 | p_i \leftarrow closest unvisited neighbor to p_{i-1};
4 | Visit p_i;
5 end for
6 return \langle p_0, \ldots, p_{n-1} \rangle
```

| (30) | I ne first few lessons |
|------|---|
| | |
| A di | ifference: |
| • | Algorithm: always output a correct result |
| • | Heuristic: idea serving as a guide to solve a problem with no guarantee of always providing a good solution |
| Corr | rectness and efficiency: |
| • | An algorithm working on a set of input does not imply it will work on all instances |
| • | Efficient algorithm totally solving a problem might not exist |
| | |
| | |
| • | An algorithm working on a set of input does not imply it will work on all instances |

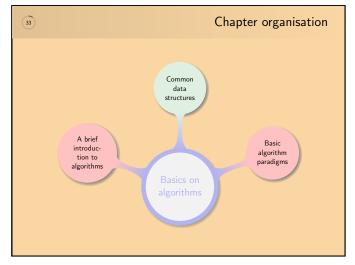

| 32 | Incorrectness |
|-------|---|
| | |
| Findi | ing good counter-examples: |
| • | Seek simplicity: make it clear why the algorithm fails |
| | Think small: algorithms failing for large Input often fail for smaller one |
| | Test the extremes: study special cases, e.g. inputs equal, tiny, huge |
| | Think exhaustively: test whether all the possible cases are covered by the algorithm |
| | Track weaknesses: check if the underlying idea behind the algorithm has any "unexpected" impact on the output |

| | |

Correctness of Kruskal's algorithm Theorem Assuming the previous notations, Kruskal's algorithm produces a minimum spanning tree for G. Proof. Let $G = \langle V, E \rangle$ be a graph and let v and w be two vertices connected by an edge. If S is the set of all the vertices with a path to v before e is added, then $w \notin S$, otherwise this would define a cycle. Moreover if there was an edge with smaller weight than e, connecting S and V - S, then it would have already been added. Therefore e is the cheapest edge connecting V - S to S, and as such belongs to a minimum spanning tree of G. Clearly by design the algorithm will not generate any cycle. Moreover as G is connected and all the edges are explored, V - S and S will be linked at some stage. Hence T is connected.

Random Access Machine (RAM) model:

Each simple operation (+, -, ×, /, if,...) takes one step

Loops are composed of several simple steps, which are repeated a certain number of times

Each memory access accounts for one step

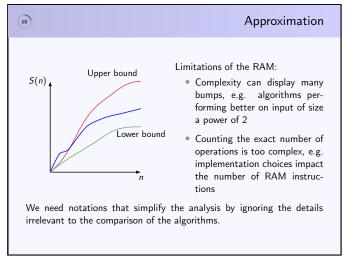

The runtime of an algorithm is given by the total number of steps necessary to complete it.

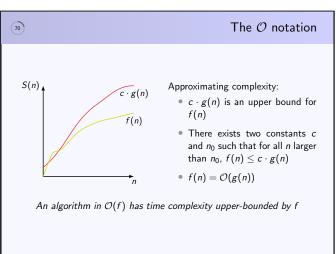

The RAM model allows the study of algorithms independently of their implementation or running environment.

Complexity for m Find

Theorem

The cost of one Find in the Union-Find data structure is $\mathcal{O}(\log n)$, while m Find operations cost $\mathcal{O}\left((m+n)\log^* n\right)$.

Proof. The rank of the root being bounded by the depth of the tree in the Union-Find data structure it is at most $\log n$.

The problem is now to evaluate the effect of m such operations. Since the path is compressed at each Find the complexity of any subsequent Find reusing a visited path is decreased.

In fact the running time of a Find operation is proportional to (i) the length of the path from a node to the root of the tree it belongs to and (ii) m.

Complexity for m Find

We now divide the nodes into "blocks", such that nodes of similar ranks are on a same block. To formerly define a block we introduce the following recursive sequence

$$\begin{cases} T_0 = 1 \\ T_i = 2^{T_{i-1}}, & i > 0. \end{cases}$$

The blocks are then defined as the sets

$$\begin{cases} B_0 = \{0\}, \ B_1 = \{1\}, \\ B_i = [T_{i-1}, T_i - 1], & i > 1. \end{cases}$$

Observing the blocks we notice that the maximum number of blocks is $\log^* n$.

Complexity for m Find

Moreover as there is a maximum of $n/2^k$ elements of rank k (lemma 2.83), the number of nodes in the i-th block is at most

$$\sum_{j=T_{i-1}}^{T_i-1} \frac{n}{2^j} = n \sum_{j=T_{i-1}}^{2^{T_{i-1}}-1} \frac{1}{2^j}$$

$$\leq \frac{2n}{2^{T_{i-1}}}$$

$$= \frac{2n}{T_i}.$$
(2.1)

The idea is to evaluate the cost of the Find while traveling from a node to its root. In such a case we traverse nodes which are (i) in the same block (ii) in a different block or (iii) directly connected to the root.

Complexity for m Find

The simplest case is (iii) as only one step is required, implying an $\mathcal{O}(m)$ complexity for the m Find.

Note that (ii) was evaluated earlier when we observed that the maximum number of blocks is $\log^* n$. Therefore the complexity of (ii) is $\mathcal{O}(m\log^* n)$.

Finally for case (i) the path starting at a node x goes through at most T_i-1-T_{i-1} ranks, and from (2.1) there are less than $2n/T_i$ such elements x in a block. Thus the total number of times the rank changes in a block is

$$(T_i - 1 - T_{i-1})\frac{2n}{T_i} \le T_i \frac{2n}{T_i}$$

$$= 2n.$$

| © Complexity for <i>m</i> Find | |
|---|--|
| Remembering that the maximum number of blocks is $\log^* n$, the Find operations generate an overall of at most $\mathcal{O}(n\log^* n)$ internal links. Hence the time spent on m operations is given by the total time spent on cases (i) to (iii), that is $\mathcal{O}\left((m+n)\log^* n\right)$. \Box For long this has been the tightest proven upper bound. However a better result was proven in the 1970's. It bounds the complexity by using the inverse Ackerman's function, which is growing even slower than the \log^* function. | |

Divide and conquer

Let S(n) be the worst-case run time for sorting an instance of size n. Simple complexity analysis:

- Time spent to divide into two pieces: $\mathcal{O}(n)$
- Time spent to solve each piece: S(n/2)
- Combine the results: $\mathcal{O}(n)$

Hence, the running time satisfies the recurrence relation

$$\begin{cases} S(2) \le c & \text{for some constant } c \\ S(n) \le 2S(n/2) + cn & \text{if } n > 2 \end{cases}$$

The Master Theorem

Let A be an algorithm whose running time is described by a recurrence of the form T(n) = aT(n/b) + f(n), with $a \ge 1$, b > 1 two constants, and f(n) an asymptotically positive function. This relation corresponds to A dividing the initial problem of size n into a sub-problems of size n/b each. While it takes T(n/b) to recursively solve each of the a sub-problems f(n) corresponds to the time spent splitting them and combining their results.

Remark. For the sake of simplicity we assume n/b to be an integer, and more generally n to be a power of b. Although it is often not true, this simplifies the discussion while having no impact on the asymptotic behavior of the recurrence.

| _ | |
|----|-----|
| 10 | . ` |
| 9: | , |

The Master Theorem

Theorem (Master theorem)

Let $a \ge 1$, b > 1, be two constants, f(n) be a function, and T(n) = aT(n/b) + f(n) be a recurrence relation over the positive integers. Then the asymptotic bound on T(n) is given by

$$T(n) = \begin{cases} \Theta(n^{\log_b a} \log n) & \text{if } f(n) = \Theta(n^{\log_b a}); \\ \Theta(n^{\log_b a}) & \text{if } f(n) = \mathcal{O}(n^{\log_b a - \varepsilon}), \ \varepsilon > 0; \\ \Theta(f(n)) & \text{if } f(n) = \Omega(n^{\log_b a + \varepsilon}), \ \varepsilon > 0, \ n \text{ large} \\ & \text{enough, and } af(n/b) \le cf(n), \ c < 1; \end{cases}$$

Back to Sort and Count

Summary of the complexity:

- $^{\bullet}$ Applying the Master theorem (2.95) to the sort part yields a complexity in $\mathcal{O}(n\log n)$
- The complexity of the merge part is in $\mathcal{O}(n)$

The overall time complexity of Sort and Count is $\mathcal{O}(n \log n)$

An obvious observation is that counting and optimization problems are closely related to search problems. As a less obvious observation one can notice that any optimization problem can be transformed into a decision problem. Example. Optimization problem: let *G* be a graph and v_1 , v_2 be two vertices in *G*. Find the shortest path between v_1 and v_2 . A corresponding decision problem: let *G* be a graph and v_1 , v_2 be two vertices in *G*. Is there a path from v_1 to v_2 that goes through less than 5 edges?

| 102 | Relation between computational problems |
|--|--|
| lem. If functio served; time al | ly any function problem can be transformed into a decision prob- the decision problem can be solved then so is its corresponding n problem. However the computational cost is not always pre- for instance a function problem might be solved by an exponential gorithm while its corresponding decision problem can be solved nomial time. |
| by com | sely decision problems can be converted into function problems puting the characteristic function of the set associated with the problem. |
| theorie | n problems play a central role in computability and complexity s. In order to study them in more details we first need to setup a recise computational model. |

...an unlimited memory capacity obtained in the form of an infinite tape marked out into squares, on each of which a symbol could be printed. At any moment there is one symbol in the machine; it is called the scanned symbol. The machine can alter the scanned symbol, and its behavior is in part determined by that symbol, but the symbols on the tape elsewhere do not affect the behavior of the machine. However, the tape can be moved back and forth through the machine, this being one of the elementary operations of the machine. Any symbol on the tape may therefore eventually have an innings.

105)

Elementary operation

Let Σ be the alphabet of symbols and Q be the set of the states. Any elementary operation is determined by the symbol read and the state $a_i \in Q$.

Three basic cases can occur:

- The symbol read is replaced by another symbol from $\Sigma \cup \{b\}$, where b represents a blank
- The head moves to the left, right, or stands still
- The machine transitions from state q_i to state q_i

This can be summarized by the following map:

$$M: (\Sigma \cup \{b\}) \times Q \longrightarrow (\Sigma \cup \{b\}) \times \{-1, 0, 1\} \times Q$$

Deterministic computation

A deterministic computation is defined by (i) an initial state q_0 and (ii) a finite sequence of elementary operations.

At the end of the sequence the tape contains an integer x written over a number of cells, all the other cells being set to b (blank). The state of the tape, x, provides the result.

Definition

A function $f: \Sigma^* \longrightarrow \Sigma^*$ is said to be *Turing computable* if there exists a Turing machine M which returns f(x) for any input x.

Remark. Church proved that any computation, in a physical sense, can be performed on a Turing machine. This is however not the case anymore for quantum computers which cannot be modeled by a Turing machine. Its quantum counterpart is called *Quantum Turing machine*.

The RAM model

The RAM consists of:

- A control unit: containing a program and a program register pointing to the instruction to be executed
- An arithmetic unit: executes all the arithmetic operations
- · A memory: divided into cells, each containing an integer
- An input unit: an input tape divided into cells and a head which reads the input
- An output unit: an output tape divided into cells and a head which writes the output

A program in the RAM model

The initial configuration of a RAM:

- All the cells are set to 0, besides the first n input cells
- The program register contains 1
- The first n cells contain the value from the n input cells

A computation consists in performing a sequence of configuration based on the program.

A program is composed of operands stored in the memory and onto which instructions can be run (e.g. LOAD, STORE, +, -, \times , /, READ, WRITE, JUMP, JZERO, JGE, HALT, ACCEPT, REJECT).

| | | |
| 120) | True quantified Boolean formula | Notes |
| Dyoblom | (True Quartified Poolean Formula (TOPE)) | |
| | (True Quantified Boolean Formula (TQBF)) ed boolean formula is a formula that can be written in the | |
| form | $Q_1x_1Q_2x_2\cdots Q_nx_n\phi(x_1,x_2,\cdots,x_n),$ | |
| | n of the Q_i is one of the quantifier \exists or \forall . | |
| Calling <i>L</i> formulae, | the language composed of the True quantified boolean decide $\it L$. | |
| Example. T | he quantified boolean formula | |
| · | $\forall x_1 \exists x_2 \forall x_3 \left((x_1 \vee \neg x_2) \wedge (\neg x_1 \wedge x_3) \right)$ | |
| is False. | | |

Observe that x_3 must be True in order for the formula to evaluate as True. However x_3 is a universally quantifiable variable.

117 – 120 30

| 121) | |
|------|--|
|------|--|

True quantified Boolean formula

Theorem

TQBF can be solved in exponential time and polynomial space.

Sketech of proof. The idea consists in exhibiting a polynomial-space algorithm that decides whether any given Quantified Boolean Formula (QBF) is true.

Consider a general input

$$\Psi = Q_1x_1Q_2x_2\cdots Q_nx_n\phi(x_1,x_2,\cdots,x_n),$$

where ϕ has m clauses. We want to use the same argument as in example 2.120, i.e. if Q_i is \forall then both formulae, with x_i replaced by 0 and 1, must evaluate as True; if Q_i is \exists then only one of them is required to be True.

122)

True quantified Boolean formula

This is achieved by "pilling off" the quantifiers one by one. Starting with Q_1 , one evaluates both

$$\Psi_{1_0}=Q_2x_2\cdots Q_nx_n\phi(0,x_2,\cdots,x_n)$$
 and

$$\Psi_{1_1}=Q_2x_2\cdots Q_nx_n\phi(1,x_2,\cdots,x_n).$$

Then compute the logical value of $\psi_{1_0} \lor \psi_{1_1}$ or $\psi_{1_0} \land \psi_{1_1}$, depending whether Q_1 is \exists or \forall .

Following this strategy all the quantifiers are recursively removed and it then suffices to solve a SAT problem.

The computational cost of such a strategy is very high since at each recursive call the problem is transformed into two new linearly smaller sub-problems, resulting in a complexity of $\mathcal{O}(2^n)$.

123)

True quantified Boolean formula

We now consider the space necessary to solve TQBF.

As Ψ_i is computed either from $\Psi_{(i+1)_0} \wedge \Psi_{(i+1)_1}$ or $\Psi_{(i+1)_0} \vee \Psi_{(i+1)_1}$, the two instances of $\Psi_{(i+1)}$ can be computed sequentially. Therefore they can use the same memory space.

However at each level of recursion the indices must be saved. This incurs an $\mathcal{O}(\log n)$ overhead, and as a result if computing Ψ_{i+1} requires space S_{i+1} then evaluating Ψ_i requires

$$S_i = S_{i+1} + \mathcal{O}(\log n).$$

Hence Ψ can be reached in $\mathcal{O}(n \log n)$ space, that is in polynomial space.

124

PSPACE completeness

Definition

① Let SPACE denote the set of all the decision problems which can be solved by a Turing machine in $\mathcal{O}(s(n))$ space for some function s of the input size n. Then PSPACE is defined as

$$\mathsf{PSPACE} = \bigcup_{l} \mathsf{SPACE}(n^k).$$

 A problem Π is PSPACE-complete if and only if (i) Π is in PSPACE and (ii) for all P in PSPACE, P can be reduced in polynomial space to Π.

Theorem

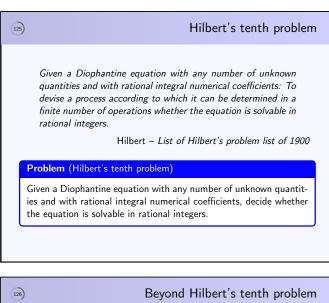

TQBF is PSPACE-complete and in particular it is \mathcal{NP} -hard.

| 3-SAT | Notes |
|--|-------|
| Problem (Satisfiability with 3 literals per clause (3-SAT)) Given a Boolean formula in CNF where each clause contains ex- | |
| actly three literals is there a truth assignment which satisfies all the clauses. | |
| 3-SAT is \mathcal{NP} -complete. | |
| Proof. Clearly 3-SAT is in \mathcal{NP} , for it is a particular case of SAT. To prove that 3-SAT is \mathcal{NP} -hard we will show that being able to solve it implies being able to solve SAT, which by Cook theorem (2.118) is known to be \mathcal{NP} -hard. | |
| 134) 3-SAT | Notes |
| Assuming CNF, we want to transform any instance of SAT into an instance of 3-SAT. Therefore we need to consider the cases where SAT has clauses with (i) one, (ii) two or (iii) more than three literals. Note that the case where there are exactly three clauses is already 3-SAT so no work is necessary. | |
| (ii) The most simple case is when there are two literals, organised in a unique disjunctive clause $x_1 \lor x_2$ denoted (x_1, x_2) . It then suffices to consider the pair of (x_1, x_2, u) and $(x_1, x_2, \neg u)$, where u is a newly added literal. | |
| (i) Similarly in the case of a single literal x we convert it into a pair of literals (x, u_1) and $(x, \neg u_1)$, for a new literal u_1 . It then suffices to apply the same strategy as above and create the four literals | |
| $(x, u_1, u_2), (x, u_1, \neg u_2), (x, \neg u_1, u_2), (x, \neg u_1, \neg u_2).$ | |

| _ | |
| | |
| | |
| | |
| | |
| | |
| | |
| | |

141

Fibonacci Numbers

- At the beginning of month 4, there are now $F_3=3$ pairs and the pair born in month 3 becomes productive.
- As the beginning of month 5, the number of pairs is equal to those
 of month 4, plus all those that were productive in month 4. These
 are all pairs that existed in month 2, since all of those will be
 productive in month 3. Hence, F₄ = 3 + 2 = 5.
- In general, at the beginning of every month the number of pairs of rabbits is equal to the number of pairs of the previous month, plus the number of pairs of two months ago, which have since become productive.

Hence,

```
F_n = F_{n-1} + F_{n-2}, \qquad n \ge 2, \qquad F_0 = 1, \qquad F_1 = 1.
```

```
Notes
```

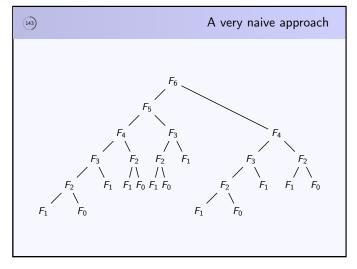

```
Algorithm.

Input: An integer n
Out- F_n
put:

1 Function \operatorname{Fib\_vn}(n):
2 | if n=0 then return 0;
3 | if n=1 then return 1;
4 | return \operatorname{Fib\_vn}(n-1) + \operatorname{Fib\_vn}(n-2)
5 end

Since F_{n+1}/F_n \approx \Phi = \frac{1+\sqrt{5}}{2} > 1.6, it means that F_n > 1.6^n.
Noting that each recursive call has to reach 0 or 1 to be completed it is clear that the complexity of this algorithm is exponential.
```

Shortest paths in weighted graphs

Problem (Shortest paths in weighted graphs)

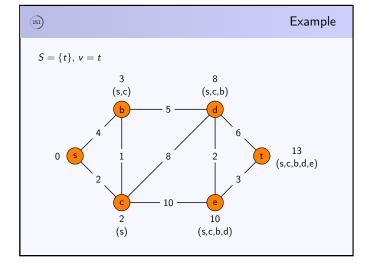

Given a connected, simple, weighted graph, and two vertices s and t, find the shortest path that joins s to t.

Two main cases for the graph:

- It only has edges with positive labels
- It has edges with positive and negative labels

We now recall Dijkstra's algorithm to solve the first case and then introduce the Bellman-Ford algorithm which takes advantage of dynamic programming in order to treat the second one.

150 Dijkstra's Algorithm Algorithm. (Dijkstra) $\textbf{Input} \quad : \mathsf{A} \; \mathsf{graph} \; \textit{G} = \langle \textit{V}, \textit{E} \rangle \; \mathsf{with} \; \mathsf{positive} \; \mathsf{edges}, \; \mathsf{two} \; \mathsf{vertices} \; \textit{s} \; \mathsf{and} \; \textit{t}$ **Output**: The shortest path between s and t1 $s.dist \leftarrow 0$; $s.prev \leftarrow NULL$; $S \leftarrow \emptyset$; 2 foreach $vertex\ v \in G.V$ do 3 | if $v \neq s$ then $v.dist \leftarrow \infty$; $v.prev \leftarrow \texttt{NULL}$; 4 | add v to S; 5 end foreach 7 repeat foreach neighbor u of v do $| tmp \leftarrow v.dist + weight(v, u);$ if tmp < u.dist then $u.dist \leftarrow tmp$; $u.prev \leftarrow v$; end foreach 12 remove v from S; $v \leftarrow$ vertex with minimal distance in S; 13 until v = t; 14 **return** t, t.prev, \cdots , s

A recursive approach

Given a reference string S and a string T we want to determine their edit distance. At each step, i.e. letter, a decision can be taken upon the previous results:

- If $S_i = T_j$, then consider $dist_{i-1,j-1}$. Otherwise consider $dist_{i-1,j-1}$ and pay a cost 1 for the difference
- If $S_{i-1} = T_j$, then it could be that T has one more character than S_{\cdot} In that case consider $dist_{i-1,j}$ and pay a cost 1 for the insertion
- ullet If $S_i=\mathcal{T}_{j-1}$, then it could be that \mathcal{T} has one less character than S. In that case consider $dist_{i,j-1}$ and pay a cost 1 for the deletion of a character in S

As those three possibilities cover all the cases, taking their minimum yields the edit distance.

of a character in ${\cal S}$

Limitations of the recursive approach

Description of the strategy:

- If either of the index is 0 then set dist to the other index

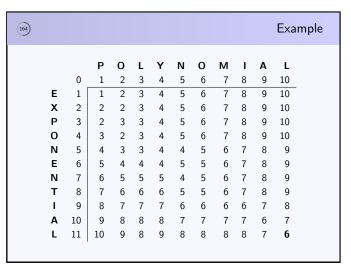

$$\label{eq:disting} \begin{split} & \overset{\cdot}{\textit{dist}}_{i,j} = \min \big(\textit{dist}_{i-1,j} + 1, \, \textit{dist}_{i,j-1} + 1, \, \textit{dist}_{i-1,j-1} + \big(\text{match} \big(\textit{S}_i, \, \textit{T}_j \big) \, ? \, \, 0 \, \, : \, \, 1 \big) \big) \end{split}$$
How fast would be the algorithm?

- At each position in the string, three branches are explored
- Only one branch reduces both indices
- Exponential time $\Omega(3^n)$

How to do better?

- What is the maximum number of pairs?
- The same pairs are recalled many times
- Use a lookup table to decrease the computational cost

Let $G=\langle V,E\rangle$ be a directed graph. We consider each node of G as a switch and each edge as carrying some traffic. This is for instance the case in the context of a highway system: nodes are the interchanges (hubs) and the edges the highway itself. It could also be illustrated using a fluid network where the edges are the pipes and the nodes the $\,$ junctures where the pipes are plugged together. To each edge one associates a number called *capacity*, which represents how much traffic an edge can handle. In the maximum network flow

Informal approach

172

problem the goal is to arrange the traffic such as optimizing the available

Before being able to solve this problem we need to formalize the idea of

|-------|
| |
| |
| |
| |
| |
| |
| |
| |
| |

Formalization

Definition

Let $G = \langle V, E \rangle$ be a weighted directed graph with a *source* node s and a sink node t; G is called a *flow network*.

Given a function $c: E \to \mathbb{R}^+$, called *capacity*, a *flow* is a function $f: E \to \mathbb{R}^+$, satisfying the following properties.

- **①** Capacity constraint: the flow of an edge can never exceed its capacity, i.e. $\forall (u,v) \in E, \ f(u,v) \leq c(u,v).$
- Flow conservation: at each node the entering flow equals the exiting flow, i.e.

$$\forall u \in V \setminus \{s, t\}, \sum_{v \in V} f(v, u) = \sum_{v \in V} f(u, v).$$

Remark. Unless specified otherwise, we restrict our attention to the case of integer or at least rational capacities and flows.

174

Formalization

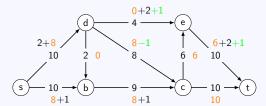

Problem (Maximum Network Flow)

Given a flow network arrange the flow such as to maximize the available capacity.

Remark. Assume a network flow is divided into two sets A and B of empty intersection and s is in A while t is in B. Intuitively any flow travelling from s to t must cross from A to B. This suggests that the capacity of the network flow can never exceed the capacity of the cuts A and B. The minimum capacity of any such division is called the minimum cut. We will prove that it is equal to the maximum flow value.

Back to the toy example

Improving the original path:

- Add +2 along $s \rightarrow d \rightarrow e \rightarrow t$; total flow: 18
- Add +1 along $s \to b \to c$: c is a bottleneck; total flow: 18
- Reallocate 1 from $d \rightarrow c \rightarrow t$ to $d \rightarrow e \rightarrow t$; total flow: 19

176

Informal strategy

Finding the maximum flow can be achieved as follows:

- Start with a null flow
- Pind paths to increase the flow:
 - Path where the capacity has not been reached
 - Reallocate flow to a different path and increase the capacity of the current one
- 3 Stop when no more flow can be injected

Goals

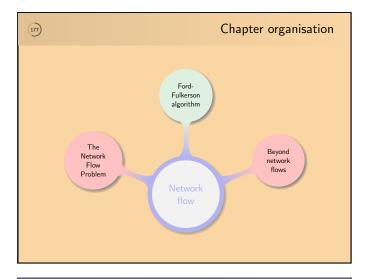

- Determine all the paths that allow an increase of the flow
- Make sure the search for such paths stops at some stage

| (1 | Mugmenting path |
|----|--|
| | Lemma |
| | The Augment algorithm (4.179) returns a flow in the original graph G. |
| | Proof. We must ensure that the output of the algorithm matches definition 4.173, that is satisfies the capacity constraint and the flow conservation properties. |
| | Consider the edges from the residual graph G_f whose capacity differ from the ones of G . In the case of e being such a forward edge with capacity $c(e)-f(e)$, we have |
| | $0 \le f(e) \le f(e) + b \le f(e) + (c(e) - f(e)) = c(e).$ |
| | If e is a backward edge then its residual capacity is $f(e)$ and |
| | $c(e) \ge f(e) \ge f(e) - b \ge f(e) - f(e) = 0.$ |
| | Hence the capacity constraint holds whether \emph{e} is a forward or backward edge. |

| 185) |
|------|
| |

Net flow across cuts

Let $G = \langle V, E \rangle$ be a flow network, s be the source, and f be a flow on G. We denote the value of the flow f by

$$|f| = \sum_{v \in V} f(s, v) - \sum_{v \in V} f(v, s).$$

We will now prove that given a flow f the net flow across any cut is the same.

Let f be a flow in a flow network $G = \langle V, E \rangle$ with source s and sink t. For any cut (S, T) of G, the net flow across (S, T) is f(S, T) = |f|.

186

Net flow across cuts

Proof. From the flow conservation (4.173) for any node $u \in V \setminus \{s, t\}$

$$\sum_{v\in V} f(u,v) - \sum_{v\in V} f(v,u) = 0.$$

Adding it to the value of the flow we get

$$|f| = \sum_{v \in V} f(s, v) - \sum_{v \in V} f(v, s) + \sum_{u \in S \setminus \{s\}} \left(\sum_{v \in V} f(u, v) - \sum_{v \in V} f(v, u) \right).$$

Rewriting the right-hand sum yields

$$|f| = \sum_{v \in V} \sum_{u \in S} f(u, v) - \sum_{v \in V} \sum_{u \in S} f(v, u).$$

187

Net flow across cuts

Noting that
$$S \cup T = V$$
 and $S \cap T = \emptyset$, the sum over the elements of V can be split over S and T to obtain
$$|f| = \sum_{v \in S} \sum_{u \in S} f(u, v) + \sum_{v \in T} \sum_{u \in S} f(u, v) - \sum_{v \in S} \sum_{u \in S} f(v, u) - \sum_{v \in T} \sum_{u \in S} f(v, u)$$
$$= \sum_{v \in T} \sum_{u \in S} f(u, v) - \sum_{v \in T} \sum_{u \in S} f(v, u) + \left(\sum_{v \in S} \sum_{u \in S} f(u, v) - \sum_{v \in S} \sum_{u \in S} f(v, u)\right)$$
$$= \sum_{v \in T} \sum_{u \in S} f(u, v) - \sum_{v \in T} \sum_{u \in S} f(v, u)$$
$$= f(S, T)$$

Hence the net flow across the cut (S, T) is the value of the flow f. \square

Upper bound on a flow

Given a flow network G and a flow f, f is upper bounded by the capacity of any cut in G.

Proof. Using lemma 4.185 and the capacity constraint (4.173) we have

$$|f| = f(S, T) = \sum_{v \in T} \sum_{u \in S} f(u, v) - \sum_{v \in T} \sum_{u \in S} f(v, u)$$

$$\leq \sum_{v \in T} \sum_{u \in S} f(u, v) \leq \sum_{v \in T} \sum_{u \in S} c(u, v)$$

$$= c(S, T)$$

| 189) | |
|----------|--|
| \smile | |

Max-flow Min-cut Theorem

From the previous lemma (4.188) we can conclude that the maximum flow is upper bounded by the capacity of a minimum cut. We now prove that they are in fact equal.

Theorem (Max-flow Min-cut Theorem)

Let f be a flow in a flow network $G = \langle V, E \rangle$, with source s and sink t. Then following conditions are equivalent.

- \oplus The residual network G_f contains no augmenting path.
- **(6)** The value of the flow |f| is equal to the capacity of some cut (S, T) of G.

Max-flow Min-cut Theorem

Proof. (i) \Rightarrow (ii): we suppose that f is a maximum flow but G_f has an augmenting path. This generates a flow with value strictly larger than |f|, which contradicts lemma 4.188.

(ii) \Rightarrow (iii) : we suppose that G_f has no augmenting path, i.e. has no path from s to t. Let $S = \{v \in V \mid \text{there is a path from } s \text{ to } v\}$, and $T = V \setminus S$.

Clearly (S, T) is a cut, since $s \in S$ and $t \not \in S$ for otherwise there would be a path from s to t.

Let $u \in S$ and $v \in T$ be a pair of vertices.

If e = (u, v) is in E then f(e) = c(e), otherwise e would be in E_f and v would be in S_{-f}

If e = (v, u) is in E then f(e) = 0, otherwise $c_f((u, v)) = f(e)$ would be positive, (u, v) would be in E_f , and v would be in S_f

Max-flow Min-cut Theorem

For the last case, note that if neither (u, v) nor (v, u) belongs to E it means that f((u, v)) = f((v, u)) = 0.

Thus we have

$$f(S,T) = \sum_{v \in T} \sum_{u \in S} f(u,v) - \sum_{v \in T} \sum_{u \in S} f(v,u)$$
$$= \sum_{v \in T} \sum_{u \in S} c(u,v) - \sum_{v \in T} \sum_{u \in S} 0$$
$$= c(S,T)$$

Therefore, by lemma 4.185, |f| = c(S, T).

 $(iii) \Rightarrow (i)$: combining lemma 4.188 with |f| = c(S, T) yields (i).

Finding paths

While the Max-flow Min-cut theorem (4.189) provides a proof of accuracy for Ford-Fulkerson algorithm (4.181), the question of its efficiency remains unanswered.

In fact the algorithm still features an unclear request: "while there is a path P in the residual graph G_f ". So the question boils down to knowing "how to determine all the paths and what is the cost".

A simple implementation of the algorithm would complete as the value of the flow keeps increasing by at least one unit while never exceeding the maximum flow f^* . Therefore in the worst case the complexity is $\mathcal{O}(|E||f^*|)$.

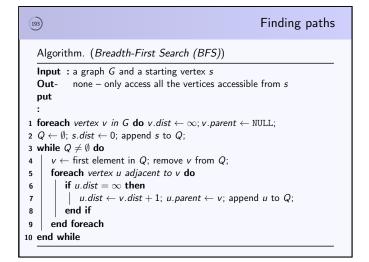

On the other hand if edges have a large capacity this strategy is not optimal and finding a "good path" becomes of a major importance. In practice this can be done using the breadth-first search algorithm which will allow us to determine the shortest path.

Finding paths

Theorem

Given a graph $G=\langle V,E\rangle$, the complexity of Breadth-First search is $\mathcal{O}(\!(E|)\!)$.

Proof. The result is straight forward as the whole adjacency list is to be scanned.

We now prove that BFS correctly computes the shortest path distance between s and any vertex v.

Shortest distance

Lemma

Let $G=\langle V,E\rangle$ be a graph and s be a source vertex in G. Upon running BFS on G, for any vertex v, the computed value v.dist is larger than the shortest-path distance between s and v.

Proof. Let δ_{ν} be the shortest distance between s and ν . We will prove the result by induction on the number of "append" operations, the hypothesis being $v.dist \geq \delta_{\nu}$.

Base case: the first element to be appended to the list is s for which $\delta_s = s.dist = 0$; for all other vertices $\delta_v \leq v.dist = \infty$.

| | 7 | 7 | ۱ |
|------|---|---|---|
| - (1 | 9 | 6 | 1 |
| | | | |

Shortest distance

Induction step: let v and u be two vertices where u is discovered from v. Noting that u.dist = v.dist + 1 we apply the induction hypothesis to v and get

 $u.dist \ge \delta_v + 1$ $\ge \delta_u$

Noting that a vertex in never appended more than once, u.dist will not be updated. Therefore the induction principle applies and for any vertex v in V, v.dist is larger than the shortest-path distance between s and v.

We now want to prove that (i) nodes in Q are ordered with respect to their distance, and (ii) the first and last have a distance difference of at most one.

| | | | | |

In order to evaluate the complexity of the Ford-Fulkerson algorithm (4.181), the question of how to find an augmenting path had to be answered.

We now prove that a shortest path in the residual network can be discovered using BFS and then used as an augmenting path. The resulting algorithm is called the Edmonds-Karp algorithm.

Lemma

Let $G=\langle V,E\rangle$ be a flow network with source s and sink t. If the Edmonds-Karp algorithm is run on G then for any vertex v in $V\setminus \{s,t\}$, the shortest-path distance $\delta_{f,v}$ in the residual network G_f increases monotonically with each flow augmentation.

Shortest path as augmenting path

The Edmonds-Karp algorithm

Proof. Suppose that there exists a vertex $v \in V \setminus \{s,t\}$ such that a flow augmentation causes the shortest-path distance between s and v to decrease

Let f and f' be the flows just before and after the augmentation that decreases the shortest-path distance, respectively. Then for v we have $\delta_{f',v} < \delta_{f,v}$. If u is the vertex visited just before v in $G_{f'}$ then $\delta_{f',u} = \delta_{f',v} - 1$.

From the choice of v, the shortest distance between s and u did not decrease on the flow augmentation. Therefore $\delta_{f,u} \leq \delta_{f',u}$ and (u,v) cannot belong to E_f . In fact if this was the case then we would have

$$\delta_{f,\nu} \le \delta_{f,u} + 1$$

$$\le \delta_{f',u} + 1$$

$$= \delta_{f',u}$$

This contradicts the assumption $\delta_{f',v} < \delta_{f,v}$.

Shortest path as augmenting path

Since (u, v) does not belong to E_f but then belongs to $E_{f'}$ it means that the flow has been increased from v to u. However as the Edmonds-Karps applies BFS to augment the flow along the shortest path we conclude that the shortest path from s to u has (v, u) as its last edge. Therefore,

$$\delta_{f,v} = \delta_{f,u} - 1$$

$$\leq \delta_{f',u} - 1$$

$$= \delta_{f',v} - 2.$$

Again this contradicts the assumption $\delta_{f',v} < \delta_{f,v}$.

Hence there exists no vertex $v \in V \setminus \{s, t\}$ such that a flow augmentation causes the shortest-path distance between s and v to decrease. \Box

Edmonds-Karp complexity

Theorem

Let $G = \langle V, E \rangle$ be a flow network with source s and sink t. If the Edmonds-Karp algorithm is run on G then it returns a maximum flow in time $\mathcal{O}(|V||E|^2)$.

Proof. Given a path P in the residual network G_f , we call an edge e such that $c_f(P)=c_f(e)$ a *critical edge*. We immediately notice that (i) such an edge disappears from the residual network as soon as an augmentation is performed along P, and (ii) at least one edge on any augmenting path is critical.

In order to determine the complexity of the Edmonds-Karp algorithm we must figure out how many flow augmentation are performed.

Edmonds-Karp complexity

Let u and v be two vertices and e=(u,v) an edge in E. Since augmenting paths are shortest paths we have $\delta_{f,v}=\delta_{f,u}+1$.

If e is a critical edge then it will disappear form the residual network as soon as the flow is augmented. It can however reappear later after the flow from u to v is decreased, that is if (v,u) is part of an augmenting path. The question is then to know how many times it can disappear and reappear.

Let f' be the flow in G when (v,u) appears in an augmenting path. Then $\delta_{f',u}=\delta_{f',v}+1$. Moreover as $\delta_{f,v}\leq \delta_{f',v}$ (4.201) we get

$$\delta_{f',u} = \delta_{f',v} + 1$$

$$\geq \delta_{f,v} + 1$$

$$= \delta_{f,u} + 2$$

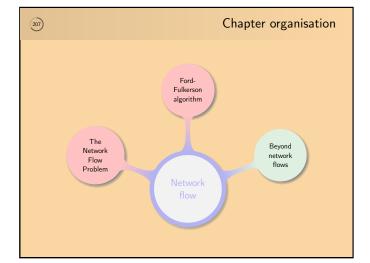

Edmonds-Karp complexity

Thus, if e is a critical edge then the next time it becomes critical the distance between the s and u has increased by at least 2, while it originally was at least 1.

Then observing that the path from s to u cannot contain u, or t, we conclude that the distance will be at most |V|-2.

Finally by combining the two bounds we conclude that an edge is critical no more than |V|/2 times. And as the number of edges in the residual network is $\mathcal{O}(\!(E|)\!)$, the total number of critical edges during the execution of the algorithm is $\mathcal{O}(\!(V||E|)\!)$.

Recalling that an augmenting path has at least one critical edge, we loop $\mathcal{O}(V||E|)$ times in the Edmonds-Karp algorithm. For each of them, BFS with complexity $\mathcal{O}(|E|)$ (theorem 4.194) is run, leading to a total cost of $\mathcal{O}(V||E|^2)$.

General view on algorithms

When studying computability theory the importance of finding similarities between problems was highlighted (2.131). The idea behind this approach is to solve new problems by deriving appropriate algorithms from known ones.

The difficulty is therefore to view a problem from a different perspective. In practice this is similar to determining polynomial reductions in computability theory (2.114): one wants to efficiently "rephrase" a given problem into an new one for which a solution is known.

We now study such an example as we solve the maximum bipartite matching problem using network flows.

209 Maximum Bipartite Matching Let $G = \langle V, E \rangle$ be a graph. $lacksquare{1}$ If $V=L\cup R$, with L and R two disjoint sets, every vertex in V has at least one incident edge, and for any edge (u, v) either $u \in L$ and $v \in R$ or $u \in R$ and $v \in L$, then G is called bipartite graph. ${f @}$ A matching is a subset ${\it M}$ of ${\it E}$ such that for any vertex ${\it v} \in {\it V}$ at most one edge in M is incident to v. 3 A maximum matching is a matching of maximum cardinality. **Problem** (Maximum Bipartite Matching Problem) Given a bipartite graph, determine a maximum matching.

Formalizing the transformation

To be able to apply Ford-Fulkerson method we formalize the transformation of a bipartite graph $G = \langle V, E \rangle$ into a network flow.

First define $G' = \langle V', E' \rangle$, with $V' = V \cup \{s, t\}$, s and t being the source and the sink, respectively. Since G is a bipartite graph V can be partitioned into two sets L and R, and

$$E' = \{(s, u) / u \in L\} \cup \{(u, v) / (u, v) \in V\} \cup \{(v, t) / v \in R\}.$$

It then suffices to assign a unit capacity to each edge in E'.

211

At this stage an important step, that should not be omitted, is to check the cost of the transformation.

Since each vertex in V has at least one incident edge, |E| is greater or equal to $\left|V\right|/2$. Thus the number of edges in G is smaller than the one in G' and $|E'| = |E| + |V| \le 3|E|$. Hence $|E'| = \Theta(|E|)$, meaning that the transformation can be efficiently performed.

Schwartz-Zippel Lemma

Definitions

- **1** A monomial is an expression of the form $\alpha \prod_{i=1}^n x_i^{\beta_i}$, where α is an element from a base field, the x_i are n variables, and the β_i are positive integers.
- ② The total degree of a monomial is $\sum_i \beta_i$.
- The total degree of a polynomial is the largest total degree among all the monomials composing the polynomial.

Lemma (Schwartz-Zippel)

Let P be a n-multivariate polynomial of total degree d, that is not identically zero, over a field \mathbb{F} . For y_1,\cdots,y_n , chosen uniformly and independently from a finite set $S\subset \mathbb{F}$,

$$Pr[P(y_1, \cdots, y_n) = 0] \le \frac{d}{|S|}$$

Schwartz-Zippel Lemma

Proof. We proceed by induction on the number of variables n.

Base case: For n=1 the result is clear as a univariate polynomial of degree d has at most d roots.

Induction step: we assume that the result is true for an (n-1)-multivariate polynomial and prove it is also true in the case of n variables.

Let k be the largest power of X_1 in any monomial composing P. Then

$$P(X_1, \dots, X_n) = \sum_{i=0}^k X_1^i Q_i(X_2, \dots, X_n).$$

By construction, Q_k is not identically zero, its total degree is at most d-k, and it has n-1 variables. Therefore by the induction hypothesis we get

$$\Pr\left[Q_k(y_2,\cdots,y_n)=0\right]\leq \frac{d-k}{|S|}.$$

231)

Schwartz-Zippel Lemma

For y_2,\cdots,y_n in \mathbb{F} , we call \mathcal{E}_1 the event $Q_k(y_2,...,y_n)=0$. Selecting y_2,\cdots,y_n such that \mathcal{E}_1 does not occur, we define $R(X_1)$ to be the polynomial

$$R(X_1) = \sum_{i=0}^k X_1^i Q_i(y_2, \dots, y_n) = P(X_1, y_2, \dots, y_n).$$

Clearly $R(X_1)$ is not identically zero since \mathcal{E}_1 did not occur, meaning that X_1^k has a non zero coefficient. Therefore

$$\Pr\left[R(y_1) = 0 \mid \neg \mathcal{E}_1\right] \leq \frac{k}{|S|}.$$

Let \mathcal{E}_2 be the event $R(y_1)=0$, which can also be stated as $P(y_1,\cdots,y_n)=0$. In order to prove the lemma it remains to bound $\Pr[\mathcal{E}_2]$.

232

Schwartz-Zippel Lemma

As we have already bounded $\Pr[\mathcal{E}_2 \mid \neg \mathcal{E}_1]$ and $\Pr[\mathcal{E}_1]$ we can rewrite $\Pr[\mathcal{E}_2]$ as

$$\begin{split} \Pr[\mathcal{E}_2] &= \Pr[\mathcal{E}_2 \wedge \mathcal{E}_1] + \Pr[\mathcal{E}_2 \wedge \neg \mathcal{E}_1] \\ &= \Pr[\mathcal{E}_2 \wedge \mathcal{E}_1] + \Pr[\mathcal{E}_2 \mid \neg \mathcal{E}_1] \Pr[\neg \mathcal{E}_1] \\ &\leq \Pr[\mathcal{E}_1] + \Pr[\mathcal{E}_2 \mid \neg \mathcal{E}_1] \\ &\leq \frac{d-k}{|S|} + \frac{k}{|S|} = \frac{d}{|S|} \end{split}$$

Hence, by the induction principle Schwartz-Zippel lemma holds.

Remark. Schwartz-Zippel lemma (5.229) says that when evaluating P at a random point there is a very low probability of finding a root. It however does not mean that a polynomial over $\mathbb R$ has finitely many roots. For instance $P(X_1,X_2)=X_1$ has infinitely many roots.

| 238 | Exercise |
|--|---|
| Apply Karger's algorithm final values for G.E . | to the following graph ${\it G}$ and find two different |
| a C | b d e |

239 Edge contraction

The process described in the function Contract of Karger's algorithm (5.237) is called edge contraction.

As observed in the previous exercise (5.238) running Karger's algorithm can lead to various values. The question is then to figure out how to retrieve the right one with high probability. In order to do this we first evaluate the cost of a contraction.

Let $G = \langle V, E \rangle$ be a multigraph. A single contraction in Karger's algorithm takes $\mathcal{O}(|V|^2)$ time.

Proof. Assuming G is represented using a linked list at each vertex, a contraction consists in merging two lists, while ensuring no loop subsists. Therefore the list is of size $\mathcal{O}(|V|^2)$.

| | \neg |
|-------|--------|
| 12 | ഹി |
| - \^- | 10) |

Probability of finding a min-cut

Let $G = \langle V, E \rangle$ be a multigraph, and (S, T) be a min-cut. Then $\Pr\left[\mathsf{Karger's\ algorithm\ ends\ with\ }(S,T)\right] \geq \frac{1}{\binom{|V|}{2}}$

Proof. First observe that if an edge (u, v) is contracted then only the cuts containing both u and v are unchanged. Therefore for Karger's algorithm to succeed the minimum cut (S, T) must remain untouched over all the random edge selections. Denoting the number of vertices by n, n-2 contractions are to be performed in order to have only two vertices left. Naming those edges $\{e_1, \dots, e_{n-2}\}$, the goal is to determine the probability to chose a proper edge at each iteration of the

| | |
| | |
| | |
| | |

| (241) | |
|----------|--|
| \smile | |

Probability of finding a min-cut

Let k denote the size of a minimum cut in G. Then the minimum degree of any vertex in G is at least k, otherwise a cut of size less than k could be exhibited by disconnecting a vertex of degree less than k. Therefore G has at least nk/2 edges.

After a contraction the new graph has one less vertex but the degree of all the vertices remains at least k. So after i steps there are n-ivertices and at least (n-i)k/2 edges.

Since any vertex has degree at least k the probability of selecting a "bad edge", assuming none has been chosen before, is 2/(n-i).

Hence we can determine the probability of never choosing a "bad edge" during the whole process and thus end with (S, T).

Probability of finding a min-cut

This probability is given by $\Pr\left[\operatorname{find}\left(S,T\right)\right] = \Pr\left[e_1,\cdots,e_{n-2} \not\in \left(S,T\right)\right]$ $= \Pr\left[e_1 \notin (S, T)\right] \prod_{i=1}^{n-3} \Pr\left[e_{i+1} \notin (S, T) \mid e_1, \dots, e_i \notin (S, T)\right]$ $\geq \prod_{i=0}^{n-3} \left(1 - \frac{2}{n-i}\right)$ $= \frac{2}{n(n-1)} = \frac{1}{\binom{n}{2}}.$

П

Probability of finding a min-cut

Since the probability of finding a min-cut is least $1/\binom{n}{2}$ it suffices to run the algorithm $I\binom{n}{2}$, for some value I. The probability of a run to succeed is then at least

 $1 - \left(1 - \frac{1}{\binom{n}{2}}\right)^{\binom{n}{2}} \geq 1 - e^{-l}.$

Therefore an appropriate choice for l is $c \ln n$, which leads to an error probability of at most $1/n^c$. Hence the total running time of Karger's algorithm is $\mathcal{O}(n^4 \log n)$.

Although this approach works well, it remains slow. The main reason is the random choice of the edge: at the beginning the multigraph features $% \left(1\right) =\left(1\right) \left(1\right) \left($ many edges and the probability of selecting an edge from a minimum cut is low. However as the process advances the probability of contracting an edge in the minimum cut grows.

Karger-Stein's algorithm

Theorem

Given a multigraph with n vertices, Karger-Stein's algorithm discovers a minimum cut in time $\mathcal{O}(n^2 \log^3 n)$, with high probability.

Sketch of proof. First note that $6 \ll |V|$ and as such finding a minimum cut by enumeration only impacts the final complexity by a constant factor.

Given a cut, observe that the probability that it survives down to t vertices is at least $\binom{t}{2}/\binom{n}{2}$. Thus for $t=n/\sqrt{2}$ the probability of success is larger than 1/2.

Since Karger-Stein's algorithm follows a divide and conquer strategy, its complexity can be expressed by a recurrence relation.

| 1 | 246 | |
|---|-----|--|
| | | |

Karger-Stein's algorithm

Then recalling that a single edge contraction costs $\mathcal{O}(n^2)$ (lemma 5.239) we get

 $T(n) = 2\left(n^2 + T\left(\frac{n}{\sqrt{2}}\right)\right).$

Hence by the master theorem (2.95) we conclude that the running time of Karger-Stein's algorithm is $\mathcal{O}(n^2\log n)$.

We now consider the success probability. First as we start with n vertices and go down to $t=n/\sqrt{2}$, the success probability is $(t/n)^2\approx 1/2$. Then at the next recursion level the graph shrinks from $n/\sqrt{2}$ to n/2 vertices, which means an overall success probability of about 1/4.

247)

Karger-Stein's algorithm

More generally assume the minimum cut to still be in the graph and let P(t) be the probability that a call to the algorithm with t vertices successfully computes it. Then $G_i,\ 1\le i\le 2$ still contains it with probability larger than a half. Therefore the probability that a recursive call succeeds is $1/2P(t/\sqrt{2})$. And since two recursive call are performed

$$P(t) = 1 - \left(1 - \frac{1}{2}P\left(\frac{t}{\sqrt{2}}\right)\right)^2.$$

Solving this recurrence relation yields $P(n) = \Omega(1/\log n).^1$ This means that Karger-Stein's algorithm needs to be run about $\log^2 n$ times in order to have an error probability of at most $\mathcal{O}(1/n)$ of preserving the minimum cut. This gives a final complexity of $\mathcal{O}(n^2\log^3 n)$.

¹This result is proven in the homework

Final remarks

Randomized algorithms:

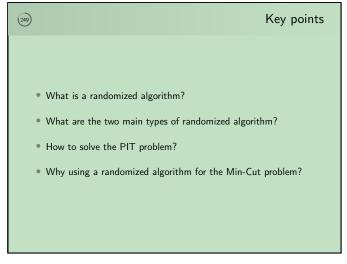

- Bring much flexibility compared to deterministic ones
- Are often faster that deterministic ones
- Introduce imprecision on the output or on the complexity
- Require a good knowledge of probability theory
- Have proof that are often complex, even if the algorithm can be simply expressed

Mathematical structures

Example. Let n be an integer, and $\mathbb{Z}/n\mathbb{Z}$ be the set of the integers modulo n

- $(\mathbb{Z}/n\mathbb{Z}, +)$ also denoted $(\mathbb{Z}_n, +)$ is a group
- $(\mathbb{Z}/n\mathbb{Z}, +, \cdot)$ is a ring
- If n is prime then $(\mathbb{Z}/n\mathbb{Z}, +, \cdot)$ is the field \mathbb{F}_n
- The invertible elements of Z/nZ, with respect to '·', form a group denoted U(Z/nZ) or sometimes Z[×]_n or Z^{*}_n
- $(\mathbb{Z}/n\mathbb{Z}[X], +, \cdot)$ is the ring of the polynomials over $\mathbb{Z}/n\mathbb{Z}$
- If n is prime and the polynomial P(X) is irreducible then

$$(\mathbb{F}_n[X]/\langle P(X)\rangle, +, \cdot)$$

is a field; this is $\mathbb{F}_{n^{\deg P(x)}}$

Roots of unity

Definitions

Let R be a ring and n be a strictly positive integer.

- **1** An element a of R is a zero divisor if there exists $b \in R \setminus \{0\}$ such that ab = 0.
- ② If 0 is the only zero divisor in R, then R is an integral domain.
- **3** An element $\omega \in R$ is an *nth root of unity* if $\omega^n = 1$.

Example.

- In \mathbb{C} , $e^{2i\pi/8}$ is a primitive 8th root of unity;
- \bullet In $\mathbb{Z}_{17},$ 2 is not a primitive 16th root of unity;

A first result

Lemma

Let R be a ring, l, n be two integers such that 1 < l < n, and ω be a primitive nth root of unity. Then (i) $\omega^l - 1$ is not a zero divisor in R, and (ii) $\sum_{j=0}^{n-1} \omega^{lj} = 0$.

Proof. (i) By definition of a primitive nth root of unity ω^I is not 1 unless I is 0 or larger or equal to n.

(ii) Note that for any $c \in R$ and m in $\mathbb N$

$$c^{m}-1=(c-1)(1+c+c^{2}+\cdots+c^{m-1}).$$

In particular for $c = \omega^I$ and m = n

$$\omega^{ln} - 1 = (\omega^l - 1)(1 + \omega^l + \dots + \omega^{l(n-1)}).$$

As $\omega^{ln}=1$, and ω^l-1 is not a zero divisor, $\sum_{j=0}^{n-1}\omega^{lj}=0$.

Discrete Fourier Transform

Definition

Let R be a ring, and $\omega \in R$ be a primitive nth root of unity. We denote a polynomial P(X) of degree less than n in R[X] by its coefficients

$$P(X) = \sum_{i=0}^{n-1} a_i X^i = (a_0, \dots, a_{n-1}).$$

The linear map

$$\mathsf{DFT}_\omega: R^n \longrightarrow R^n$$

$$(a_0, \cdots, a_{n-1}) \longmapsto (P(1), P(\omega), \cdots, P(\omega^{n-1}))$$

evaluates P at the powers of ω and is called *Discrete Fourier Transform* (DFT).

Discrete Fourier Transform

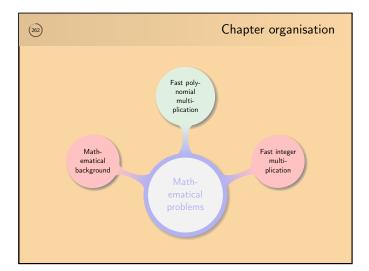

As DFT_ω is a linear map it is expressed as a matrix transformation

$$\begin{pmatrix} P(1) \\ P(\omega) \\ P(\omega^{2}) \\ \vdots \\ P(\omega^{n-1}) \end{pmatrix} = \underbrace{\begin{pmatrix} 1 & 1 & 1 & \cdots & 1 \\ 1 & \omega & \omega^{2} & \cdots & \omega^{n-1} \\ 1 & \omega^{2} & \omega^{4} & \cdots & \omega^{2(n-1)} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & \omega^{n-1} & \omega^{2(n-1)} & \cdots & \omega^{(n-1)^{2}} \end{pmatrix}}_{V} \begin{pmatrix} a_{0} \\ a_{1} \\ a_{2} \\ \vdots \\ a_{n-1} \end{pmatrix}$$

Note that if ω is a primitive nth root of unity then so is ω^{-1} . Otherwise there would be a $1 \leq k < n$ such that $(\omega^{-1})^k$ is 1. And as $\omega^n = 1$ we would have $1 = \omega^{n+k}$ and $\omega^k = 1$ _{$\pmb{\xi}$}.

Then using lemma 6.259 observe that $V_\omega V_{\omega^{-1}}=n\, {\rm I}_n$, where ${\rm I}_n$ is the identity matrix of size $n\times n$. Thus the inverse of ${\rm DFT}_\omega$ is

$$\mathsf{DFT}_\omega^{-1} = \frac{1}{n}\,\mathsf{DFT}_{\omega^{-1}}\,.$$

Representing polynomials

Two main cases depending on the structure of the polynomial:

- Dense: use an array where the coefficient of each monomial is stored at index "degree of the monomial"
- Sparse: use a structure composed of two arrays storing the degrees and the corresponding coefficients, respectively

Alternative strategy: over an integral domain a polynomial of degree strictly less than n can be represented using its value at n distinct points

Evaluating polynomials

Let $P(X) = \sum_{i=0}^n a_i X^i$ be a polynomial of degree n. Evaluating P costs $\mathcal{O}(n^2)$ if naively computed. However note that P(X) can be rewritten

$$P(X) = a_0 + X(a_1 + X(a_2 + \cdots + X(a_{n-1} + Xa_n))).$$

This remark dramatically decreases the complexity as it drops to $\mathcal{O}(n)$, and yields the following simple algorithm.

Algorithm. (Horner)

Input: a polynomial P and x the value to evaluate P at Out- Px the evaluation of P at x

put

1 Function Horner(P, x):

- $Px \leftarrow 0$;
- for $i \leftarrow \deg P$ to 0 do $Px \leftarrow Px \cdot x + \operatorname{coeff}[i]$;
- 4 return Px;

5 end

Multiplying polynomials

Two main cases depending on the polynomial representation:

- Dense: usual approach, multiply the various coefficients together; complexity $\mathcal{O}(n^2)$
- Evaluation: evaluate the polynomials in *n* points, multiply them two by two as $PQ(x_i) = P(x_i)Q(x_i)$

Complexity is $\Omega(n^2)$ since n evaluations are necessary, to which have to be added the cost of the multiplications and of the interpolation to get the final polynomial (usually $\mathcal{O}(n^2)$).

(266)

Fast Fourier Transform

Looking back at DFT_ω , it can be viewed as a special multipoint evaluation of a polynomial in the powers $1,\omega,\cdots,\dot{\omega}^{n-1}$ of a primitive nth root of unity ω . Then its inverse $\mathrm{DFT}_{\omega}^{-1}$, which given n evaluations of a polynomial allows to recover its coefficients, is just the interpolation at the powers of ω .

From the previous discussion on the DFT (6.261), it is clear that knowing how to compute it efficiently means being able to also compute its inverse

For the sake of simplicity assume $n=2^k$, $k\in\mathbb{N}$, and observe that

$$P(X) = \sum_{i=0}^{n-1} a_i X^i$$

$$= (a_0 + a_2 X^2 + \dots + a_{n-2} X^{n-2}) + (a_1 X + a_3 X^3 + \dots + a_{n-1} X^{n-1})$$

$$= P_1(X^2) + X P_2(X^2)$$
(6.1)

with both P_1 and P_2 of degree less than (n-2)/2 < n/2.

| Notes | |
|-------|--|
| | |
| | |
| | |
| | |
| | |
| | |
| | |
| | |
| | |
| | |

(267)

Fast Fourier Transform

The structure of equation (6.1) suggests a "divide and conquer" approach in order to determine

$$P(\omega^{i}) = P_{1}(\omega^{2i}) + \omega^{i}P_{2}(\omega^{2i}), \quad 0 \le i < n.$$
 (6.2)

This formulation can be further rewritten by noticing that

$$0 = \omega^{n} - 1$$

= $(\omega^{n/2} - 1)(\omega^{n/2} + 1)$.

By lemma 6.259 none of the two factors is a zero divisor and as $\omega^{n/2} \neq 1$, ω being a primitive *n*th root of the unity, we conclude that $\omega^{n/2} = -1$. Hence, for all $0 \le i < n/2$, $\omega^i = -\omega^{n/2+i}$, and (6.2) can be rewritten

$$P(\omega^{i}) = P_{1}(\omega^{2i}) + \omega^{i} P_{2}(\omega^{2i}), \quad 0 \le i < n/2,$$

$$P(\omega^{n/2+i}) = P_{1}(\omega^{2i}) - \omega^{i} P_{2}(\omega^{2i}), \quad 0 \le i < n/2.$$

Polynomial multiplication using FFT

Theorem

Let R be a ring supporting the FFT and n be 2^k , with k in \mathbb{N}^* . Then for two polynomials P and Q in R[X], with deg PQ < n, the fast polynomial multiplication algorithm computes their product in time $\mathcal{O}(n \log n)$.

Proof. The correctness of the algorithm is clear when considering the previous discussion (6.270).

The algorithm computes three DFT, n component-wise products in R, as well as n multiplications by the inverse of n in R. Therefore the overall complexity is dominated by $\mathcal{O}(n \log n)$.

Rings not supporting the FFT

In order to run the fast polynomial multiplication algorithm (6.271) the underlying ring R must support the FFT. In the case where R does not contain any primitive 2^k th root of unity a "virtual" one can be attached to the ring.

The Schönage-Strassen algorithm handles this special case at the cost of a slightly worse complexity. In fact their result states that over any ring the product of two polynomials of degree less than n can be computed in $\mathcal{O}(n\log n\log\log n)$ operations.

From polynomials to integers

Let a and b be two N-bit long integers. For the sake of simplicity we assume N to be of the form 2^{2^l} for some integer l > 0. Let a_N, \dots, a_0 and b_N, \dots, b_0 denote the binary representations of a and b, respectively. Since N was chosen to be a square it is easy to split a and b into blocks

$$\mathbf{a} = \sum_{i=0}^{\sqrt{N}-1} A_i 2^{i\sqrt{N}}, \text{ and } \mathbf{b} = \sum_{i=0}^{\sqrt{N}-1} B_i 2^{i\sqrt{N}}, \quad 0 \leq A_i, B_i \leq 2^{\sqrt{N}}-1.$$

If we consider the polynomials $A(X) = \sum_{i=0}^{\sqrt{N}-1} A_i X^i$ and $B(X) = \sum_{i=0}^{\sqrt{N}-1} B_i X^i$, then the product AB evaluated at $2^{\sqrt{N}}$ is exactly the product ab. Therefore integer multiplication can be performed via polynomial multiplication: (i) write the two integers as polynomials, (ii) apply the fast polynomial multiplication on them, and (iii) finally evaluate the product at $2^{\sqrt{N}}$.

| - | 8 | ` | ĸ | |
|----|---|----|---|--|
| 12 | 7 | 6 | ١ | |
| 1 | | ۲. | , | |

Attaching a new element

While the first step is simple to achieve the second one requires more technical considerations. In fact the two polynomials A and B are both of degree less than $2\sqrt{N}$ and as such R must contain a primitive $2\sqrt{N}$ th root of unity.

As $\mathbb Z$ does not support FFT some extra work is needed in order to attach a new "virtual" element to the ring without altering the final result.

Consider the ring $\mathbb{Z}_{2^{\sqrt{N}}+1}$ and observe that 2 is a primitive $2\sqrt{N}$ th root of unity. This is clear as $2^{\sqrt{N}}$ is -1 modulo $2^{\sqrt{N}}+1$. Thus $t=2\sqrt{N}$ is the smallest power for which 2^t is 1.

An obvious idea is then to perform the computation in the ring $\mathbb{Z}_{2^{\sqrt{N}}+1}[X].$ However as both A and B can feature coefficients as large as $2^{\sqrt{N}}-1,$ the polynomial C resulting from their product can have coefficients up to $\sqrt{N}2^{2\sqrt{N}},$ which is larger than $2^{\sqrt{N}}+1.$

Expanding the ring

As a result, if coefficients in C happen to be too large they will be reduced modulo $2^{\sqrt{N}}+1$, ruining the whole calculation. A simple solution consists in performing all the computation in a larger ring. At that stage two points must be taken into consideration: (i) the use of a large ring increases the computational cost and (ii) the ring must contain a primitive $2\sqrt{N}$ th root of unity.

Note that for any $N\geq 1$, $2^{3\sqrt{N}}>\sqrt{N}2^{2\sqrt{N}}$, while 8 is a primitive $2\sqrt{N}$ th root of unity in $\mathbb{Z}_{2^{3\sqrt{N}}+1}$. The latter being a consequence of 2 being a primitive $6\sqrt{N}$ th root of unity.

Therefore it suffices to consider A and B as polynomials over the ring $\mathbb{Z}_{2^{3\sqrt{N}}+1}[X]$. Then applying the fast polynomial multiplication algorithm (6.271) and evaluating the product at $2^{\sqrt{N}}$ yields the result.

Fast integer multiplication

Algorithm. (Fast integer multiplication)

```
Input: two N bit integers a and b, a ring R=\mathbb{Z}_{2^{3\sqrt{N}}+1},\ \omega=8 a primitive 2\sqrt{N}th root of unity

Out- c=a\cdot b
put:

1 A\leftarrow \operatorname{poly}(a); /* encode a as a polynomial */
2 B\leftarrow \operatorname{poly}(b); /* encode b as a polynomial */
3 C\leftarrow \operatorname{FPMult}(A,B,\omega);
4 c\leftarrow \operatorname{Horner}(C,2^{\sqrt{N}});
5 return c;
```

(279)

Fast integer multiplication

Theorem

Given two integers of length N in a ring R, the fast integer multiplication algorithm computes their product in $\mathcal{O}(\sqrt{N}\log\sqrt{N})$ arithmetic operations in R.

Proof. The correctness results from the previous discussion (6.275). The pre-dominant computation in the algorithm is the fast polynomial multiplication of A and B, which by theorem 6.272 takes $\mathcal{O}(\sqrt{N}\log\sqrt{N})$.

Remark. With a bit more work it is possible to determine the complexity in term of bit operations, instead of arithmetic operations. In that case the complexity becomes

$$\mathcal{O}(N \log^{2+\log_2 3-1} N)$$
.

Fast integer multiplication

Other interesting remarks:

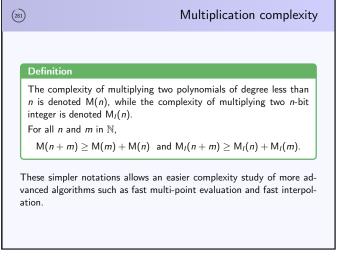

- At the bit level, most operations can be performed using "shifts", incurring a linear cost in the length of the integers. This is, in particular the main reason for choosing ω to be a power of 2.
- The integer $2\sqrt{N}$ has inverse $2^{6\sqrt{N}-\log_2\sqrt{N}-1}$ in $\mathbb{Z}_{2^{3\sqrt{N}}+1}$. Observe that $2^{6\sqrt{N}}\equiv 1 \bmod 2^{3\sqrt{N}+1}$, and $2^{\log_2\sqrt{N}}\equiv \sqrt{N}$.
- Although in the algorithm no coefficient reaches $2^{3\sqrt{N}}+1$ all the calculations are performed in the ring $\mathbb{Z}_{2^{3\sqrt{N}}+1}$ and the special case of adding two $3\sqrt{N}$ bits long elements has to be considered when defining addition.
- To date the asymptotically fastest integer multiplication algorithm, due to Fürer, takes N log N2^{O(log* N)} bit operations.

Motivating problem

A *dynamic table* is an array which automatically resizes as elements are added or removed. A common strategy consists in doubling the size of the table as soon as an overflow occurs. In such a context we want to determine the cost of n insertions.

We define the cost c_i of the ith operation to be i, if i-1 is a power of 2, and 1 otherwise. The cost C_n of n insertions is given by

$$C_n = \sum_{i=1}^n c_i$$

$$\leq n + \sum_{j=0}^{\lfloor \log(n-1) \rfloor} 2^j$$

$$\leq 3n = \Theta(n)$$

Hence the average cost for each operation is $\Theta(n)/n = \Theta(1)$.

Amortized analysis

Definition (Amortized analysis)

Given a sequence of operations, an *amortized analysis* is a strategy allowing to show that the average cost per operation is small although single operations in the sequence might be expensive.

Remark. Amortize analysis:

- · Does not uses probabilities
- Evaluates the average performance of each operation in the worst case
- Provides a more precise and useful evaluation of the difficulty of a problem than average case complexity

Common strategies

Three main approaches to amortized analysis:

- Aggregate method: most simple approach where the total running time for the sequence is analysed and divided by the number of operations
- Accounting method: charge each type of operation a constant cost such that the extra charge on inexpensive ones can be stored in a "bank" and used to pay expensive subsequent operations
- Potential method: evaluate and store the total amount of extra work done over the whole data structure and release it to cover the cost of subsequent operations

Remark. The average cost for each operation in the case of dynamic tables (7.293) was determined using the aggregate method.

Accounting method

Let c_i denote the actual real cost of the ith operation, while $\hat{c_i}$ represents its amortized cost, i being larger than 1. The goal is to always ensure that at any stage the sum of the $\hat{c_i}$ is larger than the sum of the c_i , meaning that some extra credit is available for future operations.

For a sequence of n operations the bank balance never becoming negative can be expressed as

$$\sum_{i=1}^n \hat{c}_i - \sum_{i=1}^n c_i \ge 0.$$

Example. In the case of dynamic tables (7.293) charge $\hat{c_i}=3$ units for each insertion: one is used on insertion while the 2 remaining are saved for a future use. In particular when memory is reallocated a unit is use for reassigning the current element while the last one is spent to move an older value.

| | | |
| | | |
| | | |
| | | |

Potential method

Let D_0 be an initial data structure. At step i, the ith operation, costing c_i , is applied to D_{i-1} . The potential associated with the data structure D_i , denoted $\Phi(D_i)$, is a real number and Φ is called the potential function. The amortized cost corresponds to the actual cost plus the change in potential induced by the operation. This formalizes as $\hat{c}_i = c_i + \Phi(D_i) - \Phi(D_{i-1})$, and we get

$$\begin{split} \sum_{i=1}^{n} \hat{c}_{i} &= \sum_{i=1}^{n} c_{i} + \Phi(D_{i}) - \Phi(D_{i-1}) \\ &= \sum_{i=1}^{n} c_{i} + \Phi(D_{n}) - \Phi(D_{0}) \geq \sum_{i=1}^{n} c_{i} \end{split}$$

Example. For the dynamic tables (7.293) set the potential after the ith insertion to $\Phi(D_i)=2i-2^{\lceil\log_2i\rceil}$. Then whether or not i-1 is a power of 2, the amortized cost is 3.

| 1 | - | \ |
|----|-----|----|
| (: | 298 | 3) |
| - | ٠ | ノ |

Notes

Remarks on the three methods:

- The accounting and potential methods are more powerful and refined than the aggregate one; they are equivalent in terms of applicability and precision of the bound provided
- The accounting method charges a different cost for each type of operation
- The potential method focuses on the effect of a particular operation at a specific time, and in particular on the cost of future operations
- Different methods might lead to different bounds, but always upper bound the actual cost

(299)

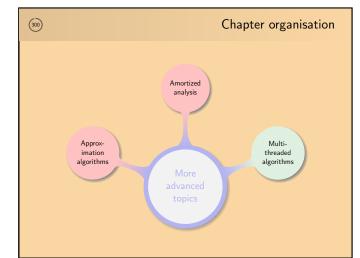

Union-Find data structure

For the Union-Find data structure (1.56), theorem 2.91 can be proven using either the accounting or the potential method.

The potential method suits this example since the goal is to determine how fast the tree is flattening, or in other words how each operation affects the whole data structure. By observing the change in potential after each type of operation it is then possible to determine the amortized cost associated with each of them.

The first and less straight forward step consists in properly setting the potential function. Two cases have to be considered (i) x is a root or has rank 0, and (ii) x is not a root and has rank larger or equal to 1. Defining the potential of x after i operations is most complicated in the latter case.

Once the potential function has been properly defined it can be bounded by $0 \le \phi_i(x) \le \alpha(n) \cdot x.rank$, and the amortized cost of the various operations can be determined.

Algorithm discussed so far targeted *uniprocessor* computers, while most modern systems feature *multiprocessors* sharing a common memory. The question is then to know how to adapt those algorithms to this new context, and in particular how to efficiently partition the work among several *threads*, each having roughly the same load.

The most simple strategy consists in employing a software layer, called *concurrency platform*, which coordinates, schedules, and manages the resources.

A simple extension to $serial\ programming$ is the addition of the following instructions: parallel, spawn, and sync.

(305)

Modeling multi-threaded algorithms

Two main strategies can be employed to avoid race conditions: (i) a thread sets a lock when reaching a critical part of the code to prevent any other thread to run it at the same time; (ii) use special hardware instructions called atomic operations which can run several operations at once.

Definition (Computation DAG)

Multi-threaded algorithms can be represented as Directed Acyclic Graph (DAG), often referred to as computation dag.

More specifically each vertex stands for an instruction while the edges organize the dependencies between the various instructions. An edge (u, v) implies that instruction u must be run before v.

A chain composed of one or more instructions and not containing any concurrency instruction is called a strand. Two strands connected by a directed path are in series, or otherwise in parallel.

(306)

Generalities

A computer composed of n processors is expected to run n concurrent threads. The scheduler is the part of the Operating System which decides which thread to run and on which CPU.

Several approaches are to be used depending on the hardware. Modern $\,$ desktop and laptop computers feature a memory shared among several CPU, which is much easier to handle than having an independent memory for each CPU.

Example. OpenMP allows to easily add parallelism to existing source code without requiring any significant rewrite. It perfectly suites systems where the memory is shared among multiple CPUs.

 $\label{eq:mpi} MPI \ of fers \ advanced \ possibilities \ more \ specifically \ targeting \ systems \ with$ a distributed memory. It is very common in the realm of high end computing, especially on clusters. MPI often requires a complete redesign, or even change of algorithm to implement.

(307)

Merge Sort

Assuming the existence of a Merge function, the following algorithm performs serial Merge Sort on a given list L.

Algorithm. (Merge Sort)

Input : $L = a_1, \dots, a_n$

Output: L, sorted into elements in non-decreasing order

Function MergeSort(L):

```
if n > 1 then
              m \leftarrow \lfloor n/2 \rfloor;
                L_1 \leftarrow a_1, \ldots, a_m; L_2 \leftarrow a_{m+1}, \ldots, a_n;
4
              L \leftarrow \texttt{Merge}(\texttt{MergeSort}(L_1), \texttt{MergeSort}(L_2))
         end if
6
7
         return L
```

The recursive calls MergeSort seem to make this algorithm a good candidate for parallelism.

(308)

Algorithm. (Merge)

Input: L_1 , L_2 , two sorted lists

Output: L a merged list of L_1 and L_2 , with elements in increasing order

1 Function Merge(L_1, L_2): $L \leftarrow \emptyset$;

```
while L_1 \neq \emptyset and L_2 \neq \emptyset do
            x \leftarrow \min(L_1, L_2);
                                                /* smallest element in \mathcal{L}_1 and \mathcal{L}_2 */
            append x to L;
5
            if L_1 = \emptyset or L_2 = \emptyset then
             L_1 = \emptyset ? append L_2 to L: append L_1 to L;
7
```

end if end while return L;

11 **end**

305 - 30877

```
Algorithm. (Parallel Merge Sort)

Input : L = a_1, \dots, a_n
Output : L, sorted into elements in non-decreasing order

1 Function P-MergeSort(L):
2 | if n > 1 then
3 | m \leftarrow \lfloor n/2 \rfloor;
4 | L_1 \leftarrow a_1, \dots, a_m; L_2 \leftarrow a_{m+1}, \dots, a_n;
5 | L_1 \leftarrow \text{spawn P-MergeSort }(L_1);
6 | L_2 \leftarrow \text{spawn P-MergeSort }(L_2);
7 | sync L \leftarrow \text{Merge }(L_1, L_2);
8 | return L;
9 | end if
10 end

In fact this parallel version does not improve much on the serial version: although Merge Sort is parallel, Merge remains serial and as such the recurrence relation still features the same \mathcal{O}(n) term. Moreover the parallelism is only \Theta(\log n).
```
